Prof Paul Strooper
Head of School
School of Information Technology and Electrical Engineering
The University of Queensland
St Lucia QLD 4072

Dear Professor Strooper,

In accordance with the requirements of the degree of Bachelor of Engineering in the school of Information Technology and Electrical Engineering, I present the following thesis entitled "Passive Radar Detection using Range-Doppler Transformations". This work was performed under the supervision of A/Prof. Vaughan Clarkson.

I declare that the work submitted in this thesis is my own, except as acknowledged in the text and footnotes, and has not been previously submitted for a degree at the University of Queensland or any other institution.

Yours sincerely,

Lewis Chambers

To Bella and Scout,
for getting me through

Acknowledgments

I would like to express my deep gratitude to A/Prof. Vaughan Clarkson, my research supervisor, for providing strong encouragement and guidance throughout the period of this work. His invaluable suggestions and willingness to give his time so generously has been greatly appreciated and extremely helpful.

I would also like to acknowledge Dr. Konstanty Bialkowski for providing me with very valuable insights into his work in the field of Passive Radar, and for teaching me about other digital communication systems throughout the last semester.

I would finally like to acknowledge the support of my family and friends for supporting me through the year and pushing me to keep working.

Abstract

This document is a skeleton thesis for 4th-year students. The printable versions (`skel.dvi, skel.ps, skel.pdf`) show the structure of a typical thesis with some notes on the content and purpose of each part. The notes are meant to be informative but not necessarily illustrative; for example, this paragraph is not really an abstract, because it contains information not found elsewhere in the document. The LaTeX 2_ε source file (`skel.tex`) contains some non-printing comments giving additional information for students who wish to typeset their theses in LaTeX. You can download the source, edit out the unwanted material, insert your own frontmatter and bibliographic entries, and in-line or `\include{}` your own chapter files. Of course the content of a particular thesis will influence the form to a large extent. Hence this document should not be seen as an attempt to force every thesis into the same mold. If in doubt about the structure of your thesis, seek advice from your supervisor.

Chapter 1

Introduction

1.1 Passive Radar

Passive radar (or passive coherent location) detection is the problem of locating unknown targets in an area of interest using only an array of static radar receivers. Using a numbers of spatially separated radar receivers, the goal is to resolve the location of target objects. The challenge lies in the fact that an active signal is not broadcast by the receivers, so they must make use of signals already permeating the air, so called illuminators of opportunity. As these signals are not generated by the receivers, they are unknown ahead of time, so must somehow be resolved from noise and reflected signals received by the radars to determine the position of targets in the area of interest.

With the advent of digital television broadcast, this technique of passive radar detection has become more viable as there are many high strength, high frequency signals being broadcast in most areas. Other examples of illuminators of opportunity include cellular phone base stations, navigations satellites and air surveillance radars [1]. Many of these transmissions are at VHF and UHF, which is optimal for radar detection. Another factor contributing to the recent feasibility of Multistatic passive radar is the requirement of suitable digital signal processing technologies, as there is large amount of data to be processed and it is a computationally significant load.

Passive radar has a number of advantages over active radar. Firstly, a passive radar system consists of only receivers, so the initial cost of implementation is lower as transmitters are not required. Secondly, many implementations of passive radar schemes require only static or non-directional receivers, so receivers need not be prohibitively expensive. Thirdly, as mentioned above, many illuminators are at VHF and UHF frequencies, where stealth treatment of targets may be less effective [2]. Finally, and most importantly, passive radar allows the covert surveillance of

an area, as it is undetectable due to the absence of a transmitter. This means that passive radar could have a variety of applications in military where a low-cost, covert, radar system is required.

Passive radar has a long history and many practical applications for the future in both military and civilian scenarios. Many factors coming together including the rise of suitable signal processing technologies and proliferation of wide band high signal strength commercial transmissions. It has been shown that passive radar is a strong candidate for a radar technology because of its covert nature and stealth-finding abilities.

1.2   Thesis definition and scope

This thesis will examine some of the current methods used to solve the Passive Radar Detection problem for the case of single static transmitter, multi-static receiver. It will analyse the effectiveness and practicality of scaling these up to very large scale deployments. It will also seek a new method that surpasses the current state of the art, for large scale utilisation.

Chapter 2

History of Radar

Radar is a system of detection that utilises pulses of radio waves to determine the distance, altitude or speed of an object. The term radar is an acronym for radio detection and ranging. The basic principle of operation of radar is fairly simple. The set-up consists of a transmitter and receiver. The transmitter generates short pulses of radio waves in the microwave spectrum, which are broadcast in the direction of interest. The receiver picks up any reflected waves that return. Computing the distance to the target can be achieved in many ways, with the most common being timing total transit time of the pulse. The distance to the target is equal to one half of the distance that light travels in the time of transit of the pulse. Other methods that can determine a target's distance or speed involve frequency modulation of the transmitted pulse, and Doppler processing of the received signal.

The earliest radar systems were bistatic, that means that the transmitter and receiver were in different locations [3]. With the advent of duplexing in radar technology, the splitting of transmit and receive operations in time over the same channel became possible, meaning that the bistatic systems could become monostatic; that is, it became possible to transmit and receive through the same antenna. Although monostatic radar has become the standard, bistatic and passive radar technologies are beginning to emerge as a topic of interest in the industry, especially in military applications [4].

The earliest passive radar systems can be found as far back as 1935, with Sir Robert Watson-Watt detecting a Heyford bomber aircraft 8km away using the illumination signal from the shortwave BBC empire transmitter [5, 6]. The interest in passive radar continued on the German side from 1943, with the Klein Heidelberg receivers used to detect British incoming aircraft, as seen in figure 2.1. Interest continued to grow in the following years and many projects followed, including Lockheed Martins Silent Sentry, an all-weather passive surveillance technology [8]. The passive system uses transmissions from multiple commercial FM radio stations to

detect airborne targets in real-time. Around this time the awareness and interest in this technology started growing rapidly, and for good reason.
Figure 2.1: German Passive Technology, the Klein Heidelberg, 1943 [7]

Passive radar technology was starting to come to the forefront, and a number of technological factors were helping. First, the appropriate signal processing power was becoming available to make the system commercially viable. Another contributing factor was the increase in high gain, high signal strength digital broadcasting frequencies, such as digital TV [9]. These have helped passive radar stay on the forefront of radar technologies.

As well as these factors, passive radar systems have many advantages over active systems. The main distinguishing factor between passive and active radar is the presence (or lack of in the case of passive), of a transmitting antenna. This leads us to the advantage that passive radar has over active radar, its ability to detect covertly. Not only is this technology covert, but it also is a cost effective counter to stealth. A system of passive receivers can track, detect and target stealth operations, as well as providing information for anti-air systems [4]. The system is also more immune to electronic counter measures (ECM), such as jamming from opposition transmitters [6]. With all of these features considered, passive radar technology has shown to have very strong military applications. Passive radar has also been used for civilian applications. PARASOL is a project sponsored by the German ministry of environmental affairs that uses passive radar for collision warning of wind power plants [5]. It employs a passive radar system that uses the DVB-T illuminators to detect aircraft approaching wind farms and also to reduce the collision of birds.

It has been shown that the predicted detection ranges for a variety of illuminators of opportunity, including analogue FM radio, cellular phone base stations and digital

audio broadcast (DAB) is in the order of 'several tens of kilometres' [10]. The signals of interest in latest works on the topic have been focused on DVB-T (Digital Video Broadcasting - Terrestrial) signals [11–14], with a higher transmitter gain and signal power, although the exact medium of the illuminating signal does not have a direct effect on the method of resolving target position and velocity.

Chapter 3

Background

3.1 Related Work

Many authors have proposed different methods of solving the problem of resolving the speed and locations of targets using a passive radar system. All system models consist of at least one passive receiver (will be denoted Rx), at least one non-cooperative transmitter or illuminator of opportunity (will be denoted Tx) and at least one target that may be stationary or moving. While these factors remain constant between methods, there are a number of choices that can be made in deriving a model. These include:

- Single receiver or multiple receiver

- Using a single illuminator or multi-band/channel illuminators

- Position of transmission source known vs unknown

- Noise variance known vs unknown

- Method for calculating position involves

  - Correlation between each Tx-Rx pair for computation
  - Correlation between each Rx-Rx pair for computation
  - A combination of both

While these are not the only choices to be made when designing a passive radar system, they are the most common considerations when employing a passive methodology. The big point of difference between many techniques is the algorithm used to detect and track target objects.

3.1.1 Problem Set-up

Many of the techniques follow similar steps to obtain the positions and speeds of targets. Initially a signal model is generated, and received signals are measured for coherence and time delay estimation [14]. To do this, signals need to be time and frequency shifted so they are in the same frame of reference. Doing this requires knowledge of the geometric location of the receivers. If a transmitter generates a signal $s(t)$, the Rx receives a time and frequency shifted version of that signal with noise, namely

$$x(t) \approx \mu s(t - \tau)e^{j\omega t} + n(t) \tag{3.1}$$

where μ is the signal amplitude, τ is the time delay, ω is the frequency shift, and $n(t)$ is the noise present in the receiver. This signal can then be time and frequency adjusted, and sampled appropriately to produce a vector

$$\bar{x}(t) \;=\; x(t + \tau)e^{-j\omega t} = \bar{\mu}s(t) + \xi(t) \tag{3.2}$$
$$\bar{x}[n] \;=\; \bar{\mu}s[n] + \xi[n] \tag{3.3}$$

The signal $\bar{x}[n]$ is the signal of interest that analysis will be performed on. In practice, we do not know ahead of time what the correcting factors τ or ω will be, so we must generate the signals $\bar{x}[n]$ for analysis for each possible time and frequency delay in a multi-dimensional grid. This is discussed further in 3.2.1, Time and Frequency Estimation.

It is also important to note that if the noise introduced is additive, white, Gaussian noise, that is not dependent on the signal $s(t)$, equation 3.2 is

We now need to manipulate these signals to perform some detection analysis, by finding the likelihood that any of the scenarios is true. This is done by comparing two hypotheses,

- the null hypothesis, where the received signals are simply given by random white gaussian noise

- the alternative hypothesis, where the received signals are correlated

These are compared by a metric known as the generalised likelihood ratio test (GLRT). This is the real distinguishing factor between methods, and there are a number of approaches of interest to this project, including:

- Generalised Canonical Correlation analysis (GCCA) for a single transmitter [11]

- Bayesian detection for signals of know rank with known and unknown noise variance [16]

- Source localisation for each Rx-Rx pair and each Tx-Rx pair [17]

- Using single frequency networks for detection [18]

This metric is then calculated over a multi-dimensional array, spanning two spatial directions and multiple frequencies. In practice, it is usually viewed as a 2-D spatial grid for each frequency. This gives us a physical view of the likelihood of a target occurring at each position in an image known as the plan position indicator (PPI) map. Some images of PPI maps appear in the Implementation section 4.2. Some methods also include post analysis on the PPI map, for a sharpened location of targets.

3.1.2 Generalised Canonical Correlation Analysis

One such method for determining a GLRT is using Generalised Canonical Correlation Analysis [11]. This method determines the likelihood based on a method that is analogous to generalised canonical correlation in multivairate stasitcs.

It is easiest to first analyse the case where there exist only two receivers, and then extend the results. Consider the two receiver case, where the received signals are $x_1(t)$ and $x_2(t)$, and the transmitter broadcasts a signal $s(t)$. Then, as above in equation 3.1, we know that the received signals are time and frequency shifted.

$$x_1(t) \approx \mu_1 s(t - \tau_1)e^{j\omega_1 t} + n_1(t) \tag{3.4}$$

$$x_2(t) \approx \mu_2 s(t - \tau_2)e^{j\omega_2 t} + n_2(t) \tag{3.5}$$

Here we know that the scalars μ_i and τ_i are different, because the receivers are spatially separated, resulting in different time delays and isotropic signal decay. The ω_i are different for the same reason, but this will be explained further in section 3.2.4.

Again, as in equation 3.2, we can correct for the time and frequency at a given hypothesis location (See section 3.2.1) by

$$\bar{x}_1(t) = x(t + \tau_1)e^{-j\omega_1 t} = \bar{\mu}_1 s(t) + \xi_1(t) \tag{3.6}$$

$$\bar{x}_2(t) = x(t + \tau_2)e^{-j\omega_2 t} = \bar{\mu}_2 s(t) + \xi_2(t) \tag{3.7}$$

Now if we take N samples from each of these $\bar{x}_i$ signals, and we know the signal variance σ^2, we can calculate the likelihood that $s(t)$ was our transmitted signal, given that we know the corrected $\bar{x}_1$ and $\bar{x}_2$. We must also consider the relative signal amplitudes, μ_1 and μ_2 in this calculation. This gives us the following likelihood

$$L(\mu_1, \mu_2, s|\bar{x}_1, \bar{x}_2) = \frac{1}{(2\pi\sigma^2)^N} \exp\left(- \frac{\|\bar{x}_1 - \mu_1 s\|^2 + \|\bar{x}_2 - \mu_2 s\|^2}{2\sigma^2}\right) \qquad (3.8)$$

We now wish to maximise this likelihood. Taking the log of this does not effect the maximisation process, so we can develop the log-likelihood

$$l(\mu_1, \mu_2, s|\bar{x}_1, \bar{x}_2) = \log\left(\frac{1}{(2\pi\sigma^2)^N}\right) - \frac{\|\bar{x}_1 - \mu_1 s\|^2 + \|\bar{x}_2 - \mu_2 s\|^2}{2\sigma^2}. \qquad (3.9)$$

Here we have some constant terms that can be ignored for the sake of maximisation. This gives us our simplified log-likelihood

$$l(\mu_1, \mu_2, s|\bar{x}_1, \bar{x}_2) = -\|\bar{x}_1 - \mu_1 s\|^2 - \|\bar{x}_2 - \mu_2 s\|^2. \qquad (3.10)$$

We wish to simplify this further. We can maximise l further by conditioning it only on s, setting

$$\mu_1 = \frac{s^\dagger \bar{x}_1}{\|s\|^2} = \frac{s^\dagger \bar{x}_1}{s^\dagger s} \qquad (3.11)$$

$$\mu_2 = \frac{s^\dagger \bar{x}_2}{\|s\|^2} = \frac{s^\dagger \bar{x}_2}{s^\dagger s} \qquad (3.12)$$

where $.^\dagger$ denotes the complex conjugate. Substituting this into l, we can eliminate μ_1 and μ_2 from the likelihood equation.

$$l(s|\bar{x}_1, \bar{x}_2) = -\left\|\bar{x}_1 - \frac{ss^\dagger}{s^\dagger s}\bar{x}_1\right\|^2 - \left\|\bar{x}_2 - \frac{ss^\dagger}{s^\dagger s}\bar{x}_2\right\|^2 \qquad (3.13)$$

This can then be expanded, and after cancelling terms, yields

$$l(s|\bar{x}_1, \bar{x}_2) = -\bar{x}_1^\dagger \bar{x}_1 - \bar{x}_2^\dagger \bar{x}_2 + \frac{s^\dagger F s}{s^\dagger s} \qquad (3.14)$$

where

$$F = \bar{x}_1 \bar{x}_1^\dagger + \bar{x}_2 \bar{x}_2^\dagger = \Phi\Phi^\dagger \qquad (3.15)$$

and Φ is the $N \times 2$ matrix given by $(\bar{x}_1 \bar{x}_2)$. Now the first two terms on the RHS of equation 3.14 are constant for any given $\bar{x}_i$, so can be ignored for the maximisation problem. So maximising the likelihood becomes the same as maximising the remaining Rayleigh Quotient term.

The maximum value of this quotient is given by the largest eigenvalue in the matrix F. Now this matrix is given by $\Phi\Phi^\dagger$ and so is an $N \times N$ matrix. However, it is also true that the largest eigenvalue of the F matrix is also equal to the largest eigenvalue of the matrix $G = \Phi^\dagger\Phi$. This matrix G is known as the Gram matrix, or the covariance matrix. For the case of two receivers, this is a 2×2 matrix, so computing the eigenvalues of G is much simpler.

Extending this idea to the case with arbitrary number of receivers, we can again form a matrix Φ, by taking the time and frequency corrected signals from each of the receivers, and and placing them into each column. So the amalgamated signals look like $\Phi = (\bar{x}_1 \bar{x}_2 \ldots \bar{x}_r)$ when there are r receivers. The $r \times r$ Gram matrix is then calculated, and the largest eigenvalue of this is computed. This is the GLRT value that is used in the PPI map.

3.2 Theory

3.2.1 Time and frequency estimation

As mentioned above, all of these methods rely on some procedure for estimating the time and frequency delays of the received signals. Since these are not known ahead of time, we must derive these based on our guesses for the position and frequency of the targets.

The first question is what range can be expected from the receivers. We can determine the distance to the horizon by [23]

$$D_h = \sqrt{2 \times H \times R_e} \qquad (3.16)$$

where D_h is the distance to the horizon in kilometres, H is the height of your receiver in kilometres, and R_e is the radius of the earth in kilometres and is equal to 6.4×10^3 km. This formula does not take into account refraction off the atmosphere, but for the purposes of passive radar detection, any signals that are refracted in this manner are going to be too weak to be useful. If we assume a receiver height of 30 m, we find that we have a distance to horizon of 19.6 or roughly 20 km. This is the value that will be used.

Next the spatial steps need to be determined. This calculation will determine the resolution that the Plan Position Indicator map will have, and is related to the sampling frequency of the receiver, f_s. The maximum distance travelled by a wave between samples is given by

$$D = \frac{C}{f_s} \tag{3.17}$$

where C is the speed of light through air. We will be working with receivers that have a sampling frequency of 8 MHz, so the maximum distance travelled between consecutive received samples is around 37.5 m. So to get maximum possible resolution and range, there must be a calculation performed for every 37.5 m block in the x- and y-directions, up to a distance of 20 km from the receiver. In other words, if a receiver is located at the origin of a Cartesian coordinate system, we must take analyse the set of points found by a grid bounded by (-20 000, -20 000), (-20 000, 20 000), (20 000, 20 000), and (20 000, -20 000), with 37.5 m spacings.[1]

If the relative locations of the transmitter and receiver are known, the time delay between the direct path signal and the theorised target path signal can be calculated. Let P_{tx} be the position of the transmitter, P_{rx} be the position of the receiver, and P_T be the theorised position of the target. Then

$$
\begin{aligned}
D_{tx:rx} &= \|P_{tx} - P_{rx}\| & (3.18)\\
D_{tx:T:rx} &= \|P_{tx} - P_T\| + \|P_T - P_{rx}\| & (3.19)\\
D_{\text{Path Difference}} &= D_{tx:T:rx} - D_{tx:rx} & (3.20)
\end{aligned}
$$

Now the path difference, coupled with the sampling frequency can tell us exactly how many samples the direct path, and target path signals are expected to be delayed by. The time taken for a signal to travel a distance D_i is given by

$$t_i = \frac{D_i}{C} \tag{3.21}$$

To convert this to a digital delay in samples, we again need to know the receivers sampling frequency, f_s. Now the number of samples it is delayed by, is simply given by

$$N_i = t_i \times f_s. \tag{3.22}$$

---

[1]This is a simplification of the scenario that aids in computation. If you wished to be more precise with the domain, you would consider a circle of radius 20 000 m centred on the origin.

So to do time estimation, we simply need to delay each of the received signals by the correct number of samples, dependent on the by the distance from the estimated target.

The next element that must be considered is frequency shifting. Frequency shifting is important because most targets of interest will be moving, and have a Doppler shift relative to the receiver. If this Doppler is not accounted for, the detection method will not be able to detect the reflected signals off the target because the signals at different receivers will not be frequency synchronised.

If we wish to shift our signal by our estimated frequency, f_x (note that this frequency shift can be positive or negative), we must first create a time vector that corresponds to our samples time. To do this, we simply take the sampling period

$$T = \frac{1}{f_s}, \tag{3.23}$$

and create a vector of times $t_v = \{0, T, 2T, \dots, (N-1)T\}$ that is the same length as our received signal (ie N samples). Then if $x(t)$ is our unshifted signal, we can obtain our shifted signal by

$$\hat{x}(t) = x(t) \times \exp(2\pi i f_x t_v) \tag{3.24}$$

where $\hat{x}(t)$, $x(t)$, and t_v are all column vectors and the multiplication is performed element wise. This produces our frequency shifted signal that we can now perform analysis on.

3.2.2 Range-Doppler Maps

Range-Doppler maps are another important idea in the development of this thesis. They are essentially another way of displaying the information about targets surrounding a receiver. They do not, however, present this information in the spatial domain, as the PPI maps do. Instead they display information in the Range-Doppler domain.

In this domain, the range axis represents the path difference (see equation 3.20) between a direct path, and a target path. The direct path (equation 3.18) is the path directly from the transmitter to the receiver, while the target path (equation 3.19) refers to any path from the transmitter, to a target, then to the receiver.

Expectantly, the Doppler axis refers to the Doppler shift that the signal experiences when it hits a moving target. Further explanation of how and why this occurs is found in section 3.2.4.

Calculation of the Range-Doppler domain is rather simple. The received signal, $x(t)$, is correlated with a time and frequency shifted version of itself,

$$\hat{x}(t) = x(t - \tau)e^{-2\pi i f_x t}. \tag{3.25}$$

Here, again τ is our time shift and f_x is our frequency shift. The value of the correlation of these two signals, $\mathrm{corr}(x, \hat{x})$, is then placed at the grid point in the Range-Doppler map corresponding to the correct time and frequency shifts.

The peaks in this plot will occur at the points where a target occurs. If we consider the case when the broadcast signal is $s(t)$, and the received signal from the direct path is $\mu_1 s(t - \tau_1)$ and the signal from one of the target paths is $\mu_2 s(t - \tau_2)e^{2\pi i f_x t}$. We know the correct time shift for the Range, or more correctly, path difference, is given by[2] $\tau_1 - \tau_2$, and the correct frequency shift is f_x, then we can calculate that

$$
\begin{align}
x(t) &= \mu_1 s(t - \tau_1) + \mu_2 s(t - \tau_2)e^{2\pi i f_x t} \tag{3.26}\\
\hat{x}(t) &= x\Big(t - (\tau_1 - \tau_2)\Big)e^{-2\pi i f_x t} \tag{3.27}\\
&= \mu_1 s\Big(t - (\tau_1 - \tau_2) - \tau_1\Big)e^{-2\pi i f_x t} + \mu_2 s\Big(t - (\tau_1 - \tau_2) - \tau_2\Big) \tag{3.28}\\
&= \mu_1 s(t - 2\tau_1 + \tau_2)e^{-2\pi i f_x t} + \mu_2 s(t - \tau_1) \tag{3.29}
\end{align}
$$

Here we can see that the first term in equation 3.26 and the last term in equation 3.29 share a common function, $s(t - \tau_1)$. This means that the correlation of x and $\hat{x}$ will be higher than for other shifts not having this commonality.

It is also worth noting that the signal x and $\hat{x}$ both contain complex values, so the resulting correlation value will also be complex. Ideally a singe real value for each hypothesis point is needed. Just taking the real part of the correlation is ignoring half of the data, and creates some unwanted behaviour near the origin of the Range-Doppler map. To avoid this, the absolute value of the correlation is taken and used.

This is not the only unwanted behaviour of this method. There are also some shadows that appear in the Range-Doppler map that do not correspond with targets. These shadows are artefacts caused by the correlation of the other terms of x and

---

[2]Note that the actual shift is $\tau_2 - \tau_1$. However, we are accounting for, and trying to undo this shift, so we must take the negation of it, $\tau_1 - \tau_2$.

$\hat{x}$. This and the unwanted behaviour near the origin is due to the signal basically being correlated with itself.

Better radar receivers can be tuned to receive only a direct path signal. These are known as omni-directional antennas. These antennas can actually receive two signals, a direct path only signal $d(t)$ and a non-directional signal $n(t)$. We can improve the behaviour of the Range-Doppler method by using one of these antennas and taking the correlations between $d(t)$ and the time and frequency corrected versions of $n(t)$.

This improves the response at the origin as well as removing any artefacts that would have occurred with the other method. We know this because we are now always correlating with the direct path signal, and not a mix of cross-terms that may be correlated at other places.

The correlation of two complex signals $x[n]$ and $y[n]$ is strictly defined as

$$R_{xy}(0) = \sum_{m=-\infty}^{\infty} x[n]y^*[n-m] \tag{3.30}$$

When we have finite signals the bounds are smaller, but we still need to calculate all of the inner product terms. Doing this naively can be quite computationally expensive. However, there is a simpler way to do this through Fourier Transforms. The Weiner-Khintchine theorem tells us that

$$\mathcal{F}\Big(R_{xy}(\tau)\Big) = G_{xy}(f) \tag{3.31}$$

Where $\mathcal{F}$ denotes the Fourier transform, and $G_{xy}(f)$ is the energy cross spectral density of x and y. This cross spectral density can also be calculated as

$$G_{xy}(f) = \mathcal{F}(x)\Big(\mathcal{F}(y)\Big)^* \tag{3.32}$$

So a faster method to calculate the correlation of two signals is given by

$$R_{xy} = \mathcal{F}^{-1}\Big(\mathcal{F}(x)\big(\mathcal{F}(y)\big)^*\Big) \tag{3.33}$$

where y is our direct path only signal, and x is our frequency corrected signal. Here we can use the fast Fourier Transform (FFT) algorithm to calculate the correlations in $O(n \log n)$ time. Another bonus of doing this, is that it calculates all of the cross correlations at once, so we do not need to do any time shifting, it happens in the FFT algorithm.

3.2.3   Radar Cross Section and Radar equation

Any analysis of radar would be remiss not to mention the Radar Cross Section (RCS) equation. This equation is a measure of how detectable an object is with a radar. The idea is to determine the cross-sectional area that hits a radar target to determine the isotropic spread of the signal. The radar equation is given by

$$P_r = \frac{P_t G_t G_r A_{eff}}{4\pi d^2} \tag{3.34}$$

where P_r and P_t are the power received and transmitted respectively (measured in Watts), G_r and G_t are the respective gains of the receiver and transmitter (as scalars), A_{eff} is the effective area of the radar antenna (in metres squared), and d is the distance between the receiver and transmitter (in metres).

This equation will be relevant when calculating the scaling value μ for the direct path signal. Here we would simply substitute in the know values P_t, G_t, G_r, A_{eff} and use $D_{tx:rx}$ as the value for d. Simulated values, however, use signal amplitude, rather than power. So we need to relate these two using the known relation

$$A = \sqrt{2P} \tag{3.35}$$

Substituting this into the equation 3.34 gives

$$A_r = \frac{A_t}{d}\sqrt{\frac{G_t G_r A_{eff}}{4\pi}} \tag{3.36}$$

$$A_r = \frac{A_t}{d}G, \tag{3.37}$$

where A_r and A_t are the amplitudes at the receiver and transmitter respectively and G is a constant that encompasses all of the scalar gains of the system.

The other consideration is how to treat signals that bounce off a target and head towards a receiver. Let a target be located at a distance of d_1 from the transmitter and d_2 from the receiver. Then the strength of the signal at the target is given by substituting d_1 into equation 3.34. Now the target acts as its own receiver and re-broadcasts the signal at this lower strength. This reflected signal is then isotropically radiated outwards. Substituting in this Radar cross section term[3] σ into the radar equation, we can determine the power received from this signal at the receiver by

---

[3]σ is measured in metres squared and is given by the cross sectional area of the target with respect to the transmitter

$$P_r = \frac{P_t G_t}{4\pi d_1^2} \sigma \frac{G_r}{4\pi d_2^2} A_{eff} \tag{3.38}$$

Again we can move this into an equation relating to amplitude rather than power, yielding

$$A_r = A_t \sqrt{\frac{G_t}{4\pi d_1^2} \sigma \frac{G_r}{4\pi d_2^2} A_{eff}} \tag{3.39}$$

$$A_r = A_t \sqrt{\frac{G_t G_r \sigma A_{eff}}{(4\pi)^2 d_1^2 d_2^2}} \tag{3.40}$$

$$A_r = \frac{A_t}{d_1 d_2} \sqrt{\frac{G_t G_r A_{eff}}{4\pi}} \sqrt{\frac{\sigma}{4\pi}} \tag{3.41}$$

$$A_r = \frac{A_t}{d_1 d_2} G\Sigma. \tag{3.42}$$

Here G is the same gain constant used above in equation 3.37, and Σ is a constant that relates only to the cross-sectional area of the target. Targets with a higher RCS will be easier to identify, because they radiate more of the transmitted signal through reflection than smaller targets.

The gain constant G, the RCS constant Σ, and the SNR (see section 3.2.5) are the parameters used to estimate the channel that is being broadcast in. The two parameters mentioned in this section are given by

$$G = \sqrt{\frac{G_t G_r A_{eff}}{4\pi}} \tag{3.43}$$

$$\Sigma = \sqrt{\frac{\sigma}{4\pi}} \tag{3.44}$$

3.2.4 Doppler Shift

The Doppler effect is the change in frequency of a wave due to the relative velocities of the source and observer. Bistatic Doppler shift is a specific example of the Doppler effect, present in systems with spatially separated transmitter and receiver, such as in Passive Radar. It can be thought of as the rate of change of the bistatic range, $D_{tx:T:rx}$, from equation 3.19. Alternatively, it can be given by

$$f_{\text{shift}} = \frac{1}{\lambda} \frac{d}{dt} \left(R_{tx} + R_{rx} \right), \tag{3.45}$$

where f_{shift} is the frequency that the signal is shifted by, λ is the transmitted signals wavelength, and R_{tx} and R_{rx} are the distances from the target to the

transmitter and receiver respectively. The derivative terms can be approximated by taking the projection of the velocity of the target onto the straight line joining the target to the receiver or transmitter.

Let the target of interest have velocity $V = (v_x, v_y)$, and the transmitter, receiver and target be located at P_{tx}, P_{rx}, and P_T respectively. Then we can approximate the derivatives by

$$\frac{dR_{tx}}{dt} = \frac{V \bullet (P_T - P_{tx})}{\|P_T - P_{tx}\|} \tag{3.46}$$

$$\frac{dR_{rx}}{dt} = \frac{V \bullet (P_T - P_{rx})}{\|P_T - P_{rx}\|} \tag{3.47}$$

where $\bullet$ denotes the vector dot product. The final unknown is λ, the transmitted signals wavelength. This is related to the centre frequency of the transmitted signal. This is the frequency band that the signal is actually broadcast on. It will be denoted by f_0 and is nominally 220 MHz for this thesis. The wavelength is related to this vale by

$$\lambda = \frac{C}{f_0}. \tag{3.48}$$

So, we can substitute all of these into the bistatic Doppler equation to get that the frequency shift at the receiver is given by

$$f_{\text{shift}} = \frac{f_0}{C}\left(\frac{V \bullet (P_T - P_{tx})}{\|P_T - P_{tx}\|} + \frac{V \bullet (P_T - P_{rx})}{\|P_T - P_{rx}\|}\right) \tag{3.49}$$

3.2.5   Signal to Noise Ratio

The final point of interest is the signal to noise ratio (SNR). This is the ratio of signal power to noise power present in the received signal and is a measure of how clean the received signal is. It is usually measured in dB. Higher SNR means that the meaningful information in the signal is more prevalent than the random noise. The noise that occurs in receivers is random Gaussian white noise due to thermal components. The power of this noise is given by the variance of the noise, so we can generate arbitrary SNR in a known clean signal. The equations relating SNR quantities are

$$\text{SNR} = \frac{P_{\text{signal}}}{P_{\text{noise}}} = \frac{\sigma^2_{\text{signal}}}{\sigma^2_{\text{noise}}} = \left(\frac{A_{\text{signal}}}{A_{\text{noise}}}\right)^2 \tag{3.50}$$

Note that the above formula uses the linear SNR. We will almost exclusively talk in dB, so to convert between the two, you simply need

$$\text{SNR}_{\text{DB}} = 10 \log_{10} \text{SNR} \tag{3.51}$$

Typical SNR values for radar receiver systems can occur anywhere between -10 and 50 dB, depending on the characteristics of the channel through which the signal is propagating[26]. This value can be greatly affected by temperature, and is known as thermal noise [27].

Chapter 4

Implementation of prior works

Before trying to develop a new method, it was important to first implement some of the previous methods that had been used to solve the problem. This posed a number of challenges, and was used as the code base for the rest of the thesis.

4.1 Simulating Signals

The first challenge in implementing a passive detection system, is simulating the environment that the signals are being transmitted in. There are many factors that must be accounted for to create a realistic simulation. The simulations used in this thesis take into account the following factors

- Relative positions of transmitter, receivers, and targets

- Sampling frequency of the receiver and carrier frequency that is being broadcast

- Signal to noise ratio at the receivers

- Radar cross section of targets and radar equation

- Doppler shift due to targets velocity

Explanation of how these are incorporated into the simulation design can be found below. The code listing for the signal generation can be found in appendix A.1.1.

4.1.1 Generating Signals

When the simulation is run, it must generate a number of signals for the transmitter to transmit. In reality, these are the signals that a digital TV, or radio station would be broadcasting. Due to the nature of the transmission schemes used, these signals

will be complex, with zero mean. These signals were simulated as complex, Gaussian random variables with zero mean and unitary variance. This can be done simply in MATLAB, with the command:

```
S = randn(Ngen,1) + 1i*randn(Ngen,1);
```

Where `S` is the signal the transmitter broadcasts, and `Ngen` is the number of samples we wish to generate. This `S` is then used to generate all of the received signals.

The format of the received signals, will be an $n \times r$ matrix, Φ, where n is the number of samples of the received signal, and r is the number of receivers. Each column of the Φ matrix corresponds to the signals received at the related receiver.

4.1.2   Relative Positions

The relative positions of the transmitter, receivers, and targets is the most important factor in developing this simulation. As mentioned in the 3.2.1, we can define the distance $D_{tx:rx}$ (see equation 3.18) for each receiver. We can also define for each receiver-target pair, the distance $D_{tx:T:rx}$ (see equation 3.19).

Initially, each receiver will be given the direct path signal from the transmitter. This is calculated by shifting the generated signal `S` by N_{Shift1} samples, defined by

$$N_{\text{Shift1}} = \left\lfloor \frac{D_{tx:rx}}{C} f_s \right\rfloor \tag{4.1}$$

where C is the speed of light in air and f_s is the sampling frequency of the receiver. Each receiver will also receive a signal emanating from each target. This signal will again be a scaled version of the generated signal `S`, this time shifted by

$$N_{\text{Shift2}} = \left\lfloor \frac{D_{tx:T:rx}}{C} f_s \right\rfloor \tag{4.2}$$

This second received signal will also have a frequency shift associated with it, dependent on the target's velocity, which is accounted for in section 4.1.4. Both of these signals will also be scaled appropriately, as discussed in section 4.1.3.

4.1.3   Radar Equation

This section directly references material covered in section 3.2.3. The implementation of these aspects was a direct implementation of the theory. A section of the code that appears in appendix A.1.1 is shown below to demonstrate this implementation.

```
% Give each receiver the signal from each target and transmitter
for trans = 1:ntx
    for rec = 1:nrx
        for targ = 1:ntarg
            R1 = DTxTarg(trans,targ);
            R2 = DRxTarg(rec,targ);
            DIST = R1 + R2;
            TIME = DIST / C;
            SAMP = round(TIME / dt);
            %Get the signal and frequency correct it
            sig = S.*exp(1i*2*pi*FShift(trans,rec,targ)*timevec);
            %Get the correct part of the signal (wrt time)
            sig = sig(1:Ngen-SAMP+1);
            AMP = GAIN*SIGMA / (R1*R2); %Signal amplitude
            phi(SAMP:end,rec) = phi(SAMP:end,rec) + AMP*sig;
        end
    end
end
```

The line `AMP = GAIN*SIGMA/(R1*R2)` relates directly to the constants G and Σ mentioned in section 3.2.3. A similar code snippet exists for the direct path signal, although is slightly simpler.

4.1.4 Frequency Shift

The frequency shift was discussed in section 3.2.4. A simple implementation of this appears in the code snippet below.

```
timevec = 0:dt:dt*(Ngen-1);
timevec = timevec';
sig = S.*exp(1i*2*pi*FShift*timevec);
```

Here `Ngen` is the length of the non frequency shifted signal, `S`. `Fshift` is the desired frequency shift, and `sig` is the resulting vector. The value `dt` is the period of the sampling rate and is equal to $\frac{1}{f_s}$.

4.2 GCCA Implementation

The full code for the implementation of the GCCA algorithm appears in appendix A.1.2. The pseudo code for the algorithm is as follows

```
for x in xrange
    for y in yrange
        for f in freqrange
            for each receiver r
                d ← distance from r to (x,y)
                n ← d/C × f_s
                sig1 ← signal received at r
                sig2 ← sig1 time shifted by n samples
                sig3 ← sig2 frequency shifted by f
                phi(r) ← sig3
            end
            G = phi × phi' (transpose)
            PPI(x,y,f) = max(eig(G))
        end
    end
end
```

This is the naive implementation of the algorithm. The output once this algorithm has been implemented is a PPI map.

Let there be five receivers located at $(x, y) = \{(0, 0), (0, 50), (0, -50), (-50, 0), (50, 0)\}$, two stationary targets at $(x, y) = \{(100, -150), (20, 100)\}$, and one transmitter located at $(x, y) = (1000, 0)$. We can simulate this scenario and develop a PPI map using the GCCA algorithm. The calculated PPI map for this situation appears in figure 4.1.

4.2.1   Target Detection in PPI map

Further investigations found that it was possible to extract the locations of the targets from the PPI map with known noise variance. This was done by using a series of image processing techniques and thresholding, the code for which appears in appendix A.1.3.

The PPI map has image dilation performed upon it using a disk structured element, and then converted to black and white using an appropriate threshold. The connected components of this threshold image are then computed, and if their area is above another threshold, they are deemed to be a target. The centre of the pixels in such connected components is then given as the location of the target. This procedure was applied to the same scenario as above, and the results are shown in figure 4.2.

4.3 Optimisation

4.3.1 Eigenvalue calculation

The largest eigenvalue computation needs to be performed on a large array of positions and frequencies, so must be done as efficiently as possible. Many different algorithms exist for computing eigenvalues of matrices. The algorithms of interest would need different properties depending on which passive radar method they were applied to. All would need to have a fast convergence rate to be considered appropriate for implementation in a real-time system. There are a number of iterative methods that could be employed, and have been employed for a variety of applications including Power iteration, Rayleigh-quotient iteration and the Lanczos algorithm for computing eigenvalues [19–21].

A method that was trialled was the power method for calculating the largest eigenvalue. This method requires a guess for the largest eigenvalue, and then converges towards it using iterative steps. When then difference between iterations falls below a threshold, the algorithm is said to have converged. This iterative method could use the previously calculated maximum eigenvalue as the initial guess for the next calculation. It was posited that this would speed up calculation of the largest eigenvalue.

However, it was found that the built-in command `eig()` in MATLAB, was far superior timewise than any m-file implementation of an iterative algorithm. This was especially the case for considering small numbers of receiver, and therefore small matrices.

4.3.2 Range-Doppler Usage

The GCCA method can also be sped up by using the Range-Doppler transformations to calculate the GLRT. This was not made clear until after the new method had been developed, so is not explored further in this thesis.

4.4 Time Complexity

Finally, an analysis of the time complexity of this algorithm was performed. It is important to note that this is not a fully optimised version of the algorithm, but the version the author was able to implement simply.

We can let the number of radar receivers be r, the maximum scanning range in both the x- and y-directions be x, the number of frequency shifts to check be f, and

the number of samples taken in a time frame be n. The number of times the inner for loop in section 4.2 is $O(x^2 f)$.

In this inner loop, we must copy the time and frequency corrected values of the signals. There are n samples so this takes $O(n)$ time. We must also perform the multiplication $G = \Phi^\dagger \Phi$. Now we know that Phi is an $n \times r$ matrix, so performing this calculation naively[1] will take $O(nr^2)$ time. We must finally calculate the largest eigenvalue of our $r \times r$ matrix G. This will take $O(r^3)$ time. So we find that the time complexity for the inner loop is given by

$$
\begin{align}
t_{\text{inner}} &= O(n + nr^2 + r^3) \tag{4.3} \\
&= O\left(n(r^2 + 1) + r^3\right) \tag{4.4} \\
&= O\left(nr^2 + r^3\right) \tag{4.5} \\
&= O\left(r^2(n + r)\right) \tag{4.6} \\
& \tag{4.7}
\end{align}
$$

In general we know that $r \ll n$, because the number of receivers is small compared to the number of samples taken. So $O(n + r)$ will always simplify to $O(n)$. So we have the time complexity of the inner loop being

$$
t_{\text{inner}} = O\left(nr^2\right) \tag{4.8}
$$

This means that the total time complexity for the naive implementation of the GCCA algorithm for solving the passive radar detection problem is

$$
O\left(x^2 f n r^2\right) \tag{4.9}
$$

[1]For non-square matrices, naive multiplication is close to the best case time complexity.

Figure 4.2: PPI indicator map for scenario detailed in section 4.2, with target detection applied

Chapter 5

Design

5.1 Motivation

The main motivation behind a new approach for passive radar detection stems from the fact that the cost of radar receivers is beginning to fall, as antenna and receiver technology gets cheaper and more efficient [24, 25]. This means that it is starting to become plausible to have large networks of cheap receivers working together as a detection system.

With this scalability in hardware, comes the need for a massively scalable algorithm for detection. The large scale of such a system presents its own problems that current detection methods will struggle with, such as

- Greater timing and synchronisation issues due to the larger number of receivers

- The need to amalgamate all the data at a centralised location for processing

- The computing power to calculate the PPI map using all of the received data

The current methods all require that the raw received data be sent and synchronised to a high degree of accuracy to the same place for processing. The main focus is to develop an algorithm that is robust to the factors mentioned above and very efficient, as it must scale well.

5.2 The Range-Doppler Transformation

The main idea behind this technique for the Passive Radar detection problem is that signals received at each receiver can be processed separately. The general process for the algorithm is as follows.

1. For each receiver, a Range-Doppler Map is calculated for each predetermined time interval

   - This calculation is performed at the receiver, meaning less time synchronisation problems

   - This is a simple calculation that utilises the FFT algorithm, as mentioned in section 3.2.2

2. The target points are detected in the Range-Doppler domain

   - These points occur as the range-frequency double (r, f)

   - This process is shown in section 5.2.1

3. The pair (r, f) in the Range-Doppler domain corresponds to an ellipse in the spatial domain

   - The ellipse is made up of all of the points that have the same path difference as (r, f)

   - The steps for determining the ellipse parameters appears in section 5.2.2

4. The ellipses are then intersected, generating a number of (x, y) spatial domain coordinates

   - These spatial domain coordinates are amalgamated into a list

   - Each pair of ellipses can intersect in up to four locations, only one of which can correspond to a target

   - The formula for intersecting ellipses is developed in section 5.2.3

5. A voting and consensus algorithm is used to determine the locations of the targets

   - The highest voted location above a threshold is deemed to be a target

   - All ellipses corresponding to this point are removed, along with all of their intersection points, and the algorithm continues

   - This continues until all targets have been found, and the highest voted location is below a threshold

   - This process is described further in section 5.2.4

5.2.1   Detecting Targets in Range-Doppler domain

Once the Range-Doppler map has been calculated, the next step is to detect the targets in this domain.

5.2.2 Generating ellipse coefficients

5.2.3 Intersecting Ellipses

5.2.4 Voting and Consensus

Putting the data together. THere is no simple way transistivity a-b¡e b-c¡e a-c¡e

5.2.5 Time complexity

A time complexity analysis was performed on the Range-Doppler transformation algorithm. As in section 4.4, we can let the number of radar receivers be r, the maximum scanning range in both the x- and y-directions be x, the number of frequency shifts to check be f, and the number of samples taken in a time frame be n.

This algorithm can perform all of the Range-Doppler map calculations simultaneously, because the data does not need to be amalgamated before computation. So for a given receiver, to calculate the Range-Doppler map, you need to calculate one FFT, and one IFFT for each frequency. The length of the FFT that is being calculated is $n + x$ because of the padding required so that when the correlation wraps around, there are no cross-terms in the calculation. The time complexity of the FFT algorithm is known to be $O n \log n$, so the time to calculate all of the Range-Doppler maps (assuming parallel computation) is

$$t_{\text{rd map}} = O\Big(f(n + x) \log(n + x) \Big) \tag{5.1}$$

Now, this can be further simplified by considering that the maximum range that is detectable, which optimally should be our value for x, is actually a function of how far the samples we have received have travelled. The furthest that a signal could have travelled is a function of how long it has travelled for, which has a direct linear relation with the number of samples received, n. So we have that x is $\Omega(n)$, so we can simplify the time to calculate the Range-Doppler maps to

$$t_{\text{rd map}} = O\Big(fn \log n \Big) \tag{5.2}$$

Detecting the peaks from these range-Doppler maps is a simple threshold ($O(x)$ and so also $O(n)$ time), and there are explicit formulas for determining the ellipse parameters, so this operation happens in constant time.

The intersection algorithm is linear in the number of intersections that occur. If we assume that each receiver has a constant maximum number of targets it can

detect, we can reason that each of the r receivers has to intersect a constant number of times with each of the other $r - 1$ receivers. This means that there are $O(r^2)$ intersections of ellipses that need to be calculated.

Finally, the voting and consensus algorithm is linear in the number of intersections, so is also $O(r^2)$. All of these operations occur consecutively, so the total time complexity for the Range-Doppler transformation algorithm is

$$t_{\mathrm{rdt}} = O\Big(fn\log(n) + n + r^2\Big) \tag{5.3}$$

$$= O\Big(fn\log(n) + r^2\Big) \tag{5.4}$$

Now in most cases the r^2 term is going to be negligible because $r^2 \ll fn\log(n)$. However, this thesis is considering the case where there are large arrays of receivers, so it would be important to note that this could become a limiting factor in the future.

This is an example picture, shown in Fig. 5.1
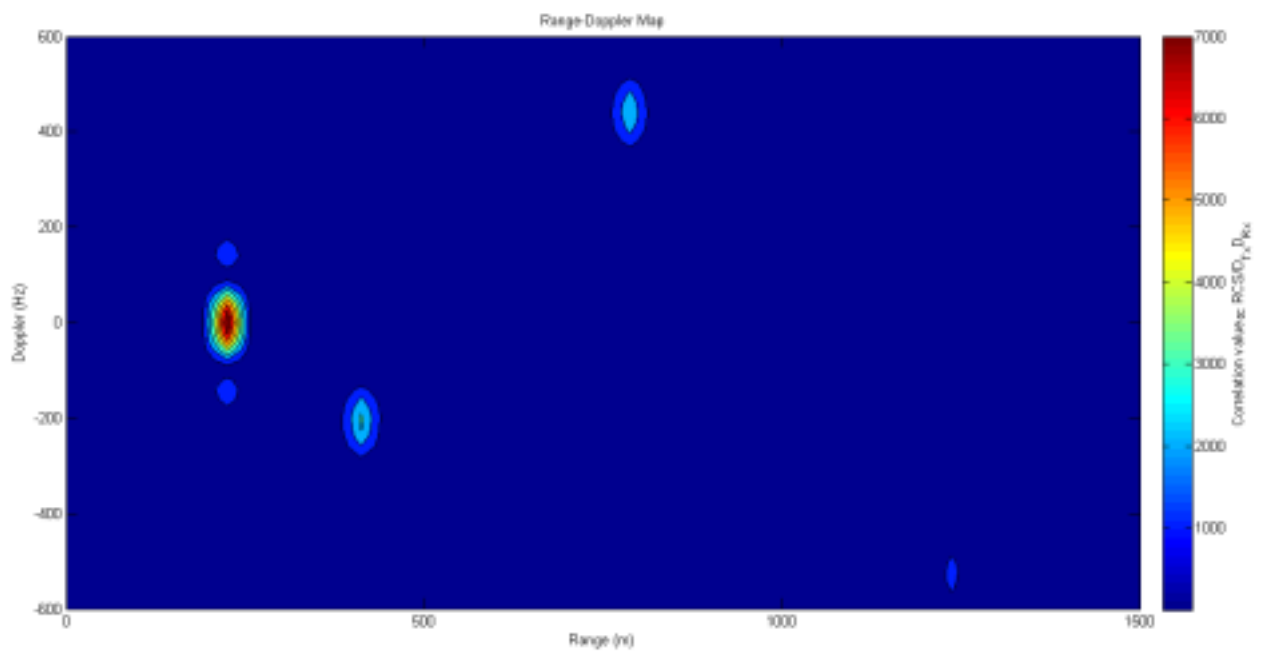

Figure 5.1: Range-Doppler Map with 4 targets

6.2   Possible future work

Appendix A

Program listings

This appendix will list some of the most important MATLAB files used in this thesis. For a full code listing, see the companion disk.

A.1 Generalised Canonical Correlation Analysis

This section will list some of the code used in making and testing the GCCA method.

A.1.1 Signal Generation

This file, `signal_gen.m`, lists the signal generation that was used for testing the GCCA algorithm

```
function [phi, direct] = signal_gen(posRx, posTx, posTarg, freq, N, noise)
%A function that generates random signal, then distributes it as well as
%off 1 target
%
%ALL DISTANCES ARE IN METRES
%
%INPUTS:
%   posRx - the position of each receiver so that posRx(1,i) and posRx(2,i)
%           are the x- and y-positions of receiver i
%   posTx - the position of the transmitter so that posTx = [xpos; ypos]
%   posTarg - the positions of the targets so that
%             posTarg(:,i) = [xpos taget i; ypos target i]
%   freq - The sampling frequency of the sampled signals
%   N - The number of samples we want generated
%   noise - Optional,
%
```

```
%OUTPUTS:
%   phi - An array of inputs from receivers in the form [X1, X2,...,Xm]
%         where Xi is a column array of values. Xi can be recovered by
%         Xi = phi(:,i)
%   direct - A vector of the direct path signal from Tx to Rx1 only

%CONSTANTS
%C = Speed of light (in m/s)

```
%Iterate through each receiver to get the time delay and calculate
%the number of samples delay to put in nset - the set of sample
delays
nset = zeros(m,1);
for rec = 1:m
    %Calculate distance along Target - Rx and time taken
    %Can ignore distance from Tx to ij as is constant for each
    %receiver and ij.
    distRx = norm(posRx(:,rec)-[i;j]);
    travel_time = distRx/C;

    %calculate n, number of samples delayed
    nset(rec) = round(travel_time / dt);
end

%time adjusted signal x'(t) and put into PHI
%Need to set maxn
%Shortest delay will be our starting point
n = min(nset);
nset = nset - n;
%Longest delay will determine how many signals we store for each
nmax = max(nset);
nstore = num_samp - nmax;

%Initialise the PHI from paper. PHI = [X1' X2' ... Xm']
%Note: here X1' does not denote transpose
PHI = zeros(nstore,m);

for rec = 1:m
    %So we can throw away the first nset samples of each signal
to
    %get all signal from the same time
    nstart = nset(rec)+1;
    PHI(:,rec) = phi(nstart:nstart+nstore-1,rec);
end
%Here we have PHI for the position (i,j)
%Calculate Gram Matrix G:
G = PHI' * PHI;
```

```
            out(iindex,jindex) = max(eig(G));
        end
end
out = out';
out = flipud(out);
```

A.1.3   Extract Targets

This file, `IP_targets.m`, determines the location of the targets from the PPI map
generated in `target_detect.m`.

```
function out = IP_targets(im)
im=imdilate(im,strel('disk',2,0));
M = round(size(im,1)/2);
N = round(size(im,2)/2);
mask = zeros(size(im));
for i=1:size(mask,1)
    for j=1:size(mask,2)
        if abs(i-M)+abs(j-N)<50
            mask(i,j) = 1;
        end
    end
end

im=im2bw(im,0.8) & not(mask);

CC = bwconncomp(im);

if CC.NumObjects == 0
    out = [];
else
    out = zeros(2,CC.NumObjects);
    for i=1:CC.NumObjects
        [x,y] = ind2sub(size(im),CC.PixelIdxList{i});
        out(:,i) = [mean(x);mean(y)];
    end
end
```

A.1.4 Analysis

This file, `test_canon.m`, sets up a scenario to run and test the GCCA algorithm.
It also performs analsis on the results and displays a graph of the findings.

```
%test_canon.m
%Test Generalised canonical correllation
%There will initially be 5 receivers spaced 50m apart located at origin
%(0,0), (0,50), (0,-50), (-50,0), (50,0)

A.2   Range-Doppler Transformation

This section will list some of the code used in making and testing the Range-Doppler Transformation method.

A.2.1   Signal Generation

The code for signal generation for the RD transformation was made a little cleaner and added some extra functionality compared with the code used for GCCA. Again this file is called `signal_gen.m`.

```
function [phi, generated, sig_noise, rxdirect] = signal_gen(posRx, posTx,
Targ, freq, carrier_freq, N, SNR)
%A function that generates random signal, then distributes it as well as
%off 1 target
%
%ALL DISTANCES ARE IN METRES
%
%INPUTS:
%   posRx - the position of each receiver so that posRx(i,1) and posRx(i,2)
%          are the x- and y-positions of receiver i
%   posTx - the position of each transmitter so that posTx(i,1) and
%          posTx(i,2) are the x- and y-positions of transmitter i
%   Targ - the positions and velovities of the targets so that
%           posTarg(i,:) = [xpos, ypos, xvel, yvel] of target i
%   freq - The sampling frequency of the sampled signals
%   carrier_freq - The carrier waves frequency
%   N - The number of samples we want generated
%   SNR - Optional - specify the SNR of the AWGN in dB. Default is 100dB
%
%OUTPUTS:
%   phi - An array of inputs from receivers in the form [X1, X2,...,Xm]
%          where Xi is a column array of values. Xi can be recovered by
%          Xi = phi(:,i)
%   direct - A vector of the direct path signal from Tx to Rx1 only
```

```
%%%%CHECK INPUTS%%%%

```

A.2.2   Range Doppler Map

This file, `rangedopplerfft.m`, calculates the Range-Doppler map from a given receiver. It uses the fast Fourier transform.

```
%Generates the range doppler map for a given receiver over a specified
%range of inputs

function [rdmap, ranges, freqs] = rangedopplerfft(phi, freq, range, freqs,
rxdirect)
%Inputs
%   phi is an Nx1 column vector of the samples received at receiver of
%   interest.
%   freq is the sampling freq in Hz
%   range is the maximum range of interest in metres. range>0
```

```
%   freqs is similar to ranges except for frequencies of interest. freqs
is
%   in Hz

%Implemented using FFT's:
%Rxy(t) = x(t) (conv) y*(-t)
%fft(Rxy) = X(f) Y*(f)
%Rxy(t) = ifft( X(f)Y*(f) )

%CONSTANTS
%C = Speed of light (in m/s)
C = 299792458;

%The period (ie time for 1 sample)
dt = 1/freq;

%Work out the maximum ranges
travel_time = range/C;
n = ceil(travel_time/dt); %The number of shifts we need to do
N = n + size(phi,1); %Size to pad to for fft

%Work out the non direct (ie target path) signal
tar = phi - rxdirect;

%Pad out the inputs so we don't get overlap in frequency domain
Fdirect = conj(fft(rxdirect,N)); %Fourier transform of direct path signal

%The range doppler map
rdmap = zeros(n,numel(freqs));

%Time vector for frequency shifting
t = 0:dt:dt*(numel(phi)-1);
t = t';

%We will be taking conjugates in frequency domain, so
freqs = -freqs;

j=0; %index
for f = freqs
```

```
    j=j+1; %index

    %frequency correct the signal
    fc_sig = tar.*exp(-1i*2*pi*f*t);

    %Compute conjugate of FFT
    Fsig = fft(fc_sig,N);

    %Find the correlation for all ranges
    cor = ifft(Fdirect.*Fsig);

    rdmap(:,j) = cor(1:n);
end

%Get real values
rdmap = abs(rdmap);
% rdmap = abs(rdmap) + real(rdmap);

%return the ranges
ranges = linspace(0,range,n);
```

A.2.3   Generate Receiver Array

This file, `getMultRXPos.m`, generates all of the receiver positions in an array.

```
function posRx = getMultRXPos(nx, ny, Rdist)
%Takes a number of points in the x- and y- directions and a distance
%between them and returns an (nx*ny)-by-2 array containing all of the
%locations of the receivers

XS = (nx-1)*Rdist;
YS = (ny-1)*Rdist;
XV = linspace(-XS/2, XS/2, nx);
YV = linspace(-YS/2, YS/2, ny)';
XA = repmat(XV,ny,1);
YA = repmat(YV,1,nx);

posRx = [XA(:), YA(:)];
```

A.2.4   Target Detection

This file, `detectTarg`, detects the locations of targets in the area from the range-doppler map.

```
function [rdHits, rdMapDetect] = detectTarg(rdmap, ranges,freqs, SNR, PSNR)
%Detects the locations of targets in the area from the range-doppler map
%using the coefficients of P, that are calculated in the function
%detectModel.
%
%rpmap is a range doppler map
%ranges are the set of ranges that the rdmap takes up
%   size(rdmap,1)==size(ranges,2)
%P = [snrs, level] where snrs is an mx1 matrix with possible SNR values
and
%level is and m-by-1 matrix with the corresponding noise floor.
%SNR is the SNR level where the map was recorded
%
%rdHits is the resulting target in the for [Range, Doppler]
%rdMapDetect is the same size as rdmap that is passed into the function
but
%with 1's where the targets are and 0's elsewhere

if nargin < 5
    load('PSNR.mat')
end

scale = 20; %The error factor in the model

%We first truncate all non interesting information
%find the noise floor
snrs = PSNR(:,1);
[~,idx] = min(abs(snrs-SNR));
cutOff = scale * PSNR(idx,2);

trunc = rdmap > cutOff;

%Do some Image processing techniques to get hits
s  = regionprops(trunc', 'centroid');
cent = round(cat(1, s.Centroid));
```

```
rdMapDetect = zeros(size(rdmap));
for i=1:size(cent,1)
    rdMapDetect(cent(i,1),cent(i,2)) = 1;
end

%Now do the processing for the maximum points
[m, id] = max(rdmap,[],2);
ids = m > cutOff;
ID = id(ids);

%Care for the case where there are no targets
if numel(cent)==0
    rdHits = [];
else
    rdHits = [ranges(ids)', freqs(ID)'];
end

% figure;
% subplot(1,2,1); imagesc(rdmap');
% subplot(1,2,2); imagesc(cutOff'); pause;
```

A.2.5 Determine Ellipse Parameters

This function, `getEllParam.m`, returns the parameters for an ellipse with given constraints.

```
function param = getEllParam(posRx, posTx, pd)
%Gets the ellipse parameters in a common form from
%   Receiver position (posRx)
%   Transmitter position (posTx)
%   path difference as calculated in the range doppler map (pd)
%
%param = [qxx, qyy, qxy, qx, qy, q0] where the ellipse ifs given by:
%
% qxx*x^2 + qyy*y^2 + qxy*x*y + qx*x + qy*y + q0 = 0;

%Extract the positions
x0 = posRx(1); y0 = posRx(2);
x1 = posTx(1); y1 = posTx(2);
```

```
%Find middle of ellipse
xm = (x0+x1)/2;
ym = (y0+y1)/2;

DTxRx = norm(posRx - posTx);

%Find angle alpha
alpha = atan((y1-y0)/(x1-x0));

%Find semimajor radii
A = (DTxRx + pd)/2;
f = DTxRx/2;
B = sqrt(A^2-f^2);

ca = cos(alpha);
sa = sin(alpha);
%Get the product terms
qxx = (ca/A)^2 + (sa/B)^2;
qyy = (sa/A)^2 + (ca/B)^2;
qxy = 2*ca*sa/A^2 + -2*ca*sa/B^2;
qx = (-2*xm*ca^2 - 2*ym*ca*sa)/A^2 + (-2*xm*sa^2 + 2*ym*ca*sa)/B^2;
qy = (-2*ym*sa^2 - 2*xm*ca*sa)/A^2 + (-2*ym*ca^2 + 2*xm*ca*sa)/B^2;
q0 = (xm^2*ca^2 + 2*xm*ym*ca*sa + ym^2*sa^2)/A^2 + (xm^2*sa^2 - 2*xm*ym*ca*sa
+ ym^2*ca^2)/B^2 - 1;

param = [qxx, qyy, qxy, qx, qy, q0];
```

A.2.6   Ellipse Intersections

This file, `findEllIntersect.m`, finds the intersection of two ellipses.

```
function out = findEllIntersect(Qparam, Rparam)
%Finds the intersection of 2 ellipses given their parameters:
%param = [qxx, qyy, qxy, qx, qy, q0] where the ellipse ifs given by
%qxx*x^2 + qyy*y^2 + qxy*x*y + qx*x + qy*y + q0 = 0;
%
%out = a n-by-2 array where n is the number of intersections
%   0<=n<=4
%   first col is x coord, second col is y coord
```

```
%Get q components
qxx = Qparam(1);
qyy = Qparam(2);
qxy = Qparam(3);
qx = Qparam(4);
qy = Qparam(5);
q0 = Qparam(6);
%Get r components
rxx = Rparam(1);
ryy = Rparam(2);
rxy = Rparam(3);
rx = Rparam(4);
ry = Rparam(5);
r0 = Rparam(6);

z4 = (- qxx^2*ryy^2 + qxx*qxy*rxy*ryy + 2*qxx*qyy*rxx*ryy - qxx*qyy*rxy^2
- qxy^2*rxx*ryy + qxy*qyy*rxx*rxy - qyy^2*rxx^2);
z3 = (qx*qxx*rxy*ryy - 2*qy*qyy*rxx^2 - qxy^2*rxx*ry - 2*qxx^2*ry*ryy -
qxx*qy*rxy^2 - 2*qx*qxy*rxx*ryy + qx*qyy*rxx*rxy + qxx*qxy*rx*ryy +
 qxx*qxy*rxy*ry - 2*qxx*qyy*rx*rxy + qxy*qy*rxx*rxy + qxy*qyy*rx*rxx +
2*qxx*qy*rxx*ryy + 2*qxx*qyy*rxx*ry);
z2 = (q0*qxy*rxx*rxy - qy^2*rxx^2 - q0*qxx*rxy^2 - 2*q0*qyy*rxx^2 -
qxx*qyy*rx^2 - qxy^2*r0*rxx - 2*qxx^2*r0*ryy - qx^2*rxx*ryy -
qxx^2*ry^2 + qxx*qxy*r0*rxy + 2*q0*qxx*rxx*ryy + 2*qxx*qyy*r0*rxx +
qx*qxx*rx*ryy + qx*qxx*rxy*ry - 2*qx*qxy*rxx*ry + qx*qy*rxx*rxy +
qx*qyy*rx*rxx + qxx*qxy*rx*ry - 2*qxx*qy*rx*rxy + qxy*qy*rx*rxx +
2*qxx*qy*rxx*ry);
z1 = (q0*qx*rxx*rxy - qxx*qy*rx^2 - 2*qxx^2*r0*ry - qx^2*rxx*ry -
2*q0*qy*rxx^2 - 2*q0*qxx*rx*rxy + q0*qxy*rx*rxx + qx*qxx*r0*rxy -
2*qx*qxy*r0*rxx + qxx*qxy*r0*rx + 2*q0*qxx*rxx*ry + 2*qxx*qy*r0*rxx +
qx*qxx*rx*ry + qx*qy*rx*rxx);
z0 = - q0^2*rxx^2 + q0*qx*rx*rxx + 2*q0*qxx*r0*rxx - q0*qxx*rx^2 -
qx^2*r0*rxx + qx*qxx*r0*rx - qxx^2*r0^2;

Ys = roots([z4 z3 z2 z1 z0]);

NY = numel(Ys);

sols = [];
```

```matlab
for i=1:numel(Ys)
    y = Ys(i);
    w0 = q0 + qy*y + qyy*y^2;
    w1 = qxy*y + qx;
    w2 = qxx;
    Xs = roots([w2 w1 w0]);
    sols = [sols; [Xs, [y;y]]];
end

%Check which are valid solutions
Q = @(x,y) (q0+qy*y+qyy*y^2) + (qxy*y + qx)*x + (qxx)*x^2;

    qval = abs(Q(sols(i,1),sols(i,2)));
    rval = abs(R(sols(i,1),sols(i,2)));
    im1 = abs(imag(sols(i,1)));
    im2 = abs(imag(sols(i,2)));
    if (qval<tol && rval<tol) && (im1<tol && im2<tol)
        out = [out; sols(i,:)];
    end
end

%Find unique up to 5 digits
n = 10^5;
rounded = real(floor(out*n)/n);
[~,ids,~] = unique(rounded,'rows');

out = real(out(ids,:));
```

A.2.7   Vote and Consensus

This file, `getTargetLocation.m`, applies the intersection, voting and consensus algorithm.

```matlab
function target = getTargetLocation(rx)
```

```
%A function that determines the likely positions of targets from an array
%of static radar receivers
%
%rx is a struct array with feild ellParam describing the parameters of
%an ellipse for each hit in the range doppler domain

%Minimum distance between any 2 intersections of ellipses
%Should be a funcion of the sampling rate

num2str(ID2)]);
```

Appendix B

Companion disk

The companion disk contains all of the This disk is also available online at https://github.com/lewythefly/ENGG4801-Passive-Radar-Detection

If you wish to make some computer files available to your examiners, you can list and describe the files here. The files can be supplied on a disk and inserted in a pocket fixed to the inside back cover.

The disk will not be needed if you can specify a URL from which the files can be downloaded.
